Which source bounds retain the volume?

One original marked source, seventeen regions

Width 3; word $O(EO)^3$, with $O = (1,3)$, $E = (0,2,4)$.
All faces, targets and the two protected zeros stay shared.

One right anchor; all other regions bounded in full

$$\inf_L C_{12,R}(L) > \Phi_D + 0.025$$

An exact feasible flow proves that no radius choice can pass.

Refine genuine source labels at four regions

At $J = \{2,4,7,12\}$ retain right versus central/left.
15 nonempty right subsets $+$ 25 remaining anchors.

These forty branches cover every noncentral source string.

One shared rational radius vector per branch

$$\Phi_D > 19.90751095350, \quad \max_B G_B(L^B) < 19.85303956990$$

Gap > 0.04 from rational data and interval bounds.
With a knot pairing, long fixed twists give the volume limit.

A different source: fifty-four crossing regions

left at region 32, central at the other 53 regions.
This genuine sector is nonzero at large even levels.

$$\inf_L G_\sigma(L) > \Phi_D + \frac{1}{5}$$

Refining these three labels cannot lower its envelope.
The signed-source estimate remains a separate question.
