The actual scalar polynomial

$p_a(z)$ has all zeros above 2.
Its canonical action generates the four-parabolic character relation.

The original resolvent

$(zI - \Omega)^{-1}$ retains the spectral poles, colliding channels and all required generic normals.

$$p_a(\Omega) = \frac{1}{2\pi i} \oint_\Gamma p_a(z)(zI - \Omega)^{-1}\, dz$$

Endpoint estimates retain the shrinking gap at 2.
Dots show the spectral regions schematically, not a fixed-level distribution.

OPEN: the original global period

A justified contributing contour, its nonzero amplitude, and the surrounding coherent contraction.
